ABSTRACT - A high-resolution palaeomagnetic intensity study of 160 discrete samples from an archaeological excavation near Piatra Neamt (Romania) gives the opportunity to compare the palaeointensity signal from this sequence to reference data from sites with established age control. We correlate the relative palaeointensity record obtained from the Poiana Cireşului site to reference data, discuss our correlation and the possibility of indirect dating of (archaeology bearing) loess by the way of palaeomagnetic intensity signal comparison. The obtained age model supports dating by means of luminescence and radiocarbon techniques. Within the palaeomagnetic record we find the Mono Lake excursion and possibly also the Laschamp excursion, which represent the most important palaeomagnetic time markers of the Late Upper Pleistocene.

ZUSAMMENFASSUNG - Eine hochauflösende paläomagnetische Intensitätsstudie an 160 Einzelproben einer archäologischen Grabung bei Piatra Neamt (Rumänien) gibt die Möglichkeit, das Paläointensitätssignal des Erdmagnetfeldes mit datierten Referenzdaten zu vergleichen. Wir korrelieren das Paläointensitätssignal aus der Grabung Poiana Cireşului mit datierten Referenzdaten und diskutieren unsere Zuordnung und die Möglichkeit der indirekten Datierung von (archäologische Funde enthaltenden) Lössen durch die Korrelation des relativen Paläointensitätssignals. Das gewonnene Zeitmodell stützt Datierungen mittels Lumineszenztechniken und der Radiokohlenstoffmethode. In der paläomagnetischen Zeitreihe sehen wir wahrscheinlich Signale der Mono Lake und Laschamp geomagnetischen Exkursionen, welche die wichtigsten paläomagnetischen Zeitmarker des späten Oberpleistozän darstellen.

KEYWORDS - palaeomagnetism, relative palaeointensity, geomagnetic excursions, Upper Palaeolithic chronology, loess, Romania

Introduction

The appearance of Upper Palaeolithic cultures and their temporal evolution is precisely recorded in

Upper Würmian loess deposits throughout eastern and central Europe. Loess is an ideal archive not only for the remains of Palaeolithic cultures. Loess is an aeolian sediment occurring predominantly in the Quaternary, it is defined as aeolian transported silt which underwent a special diagenetic process called

*corresponding author:
christianzeeden@yahoo.de

"loessification" after deposition. Silt size sediment is blown out of river floodplains (and dried endorheic basins), and accumulates in Western Eurasia predominantly in the vicinities of fluvial systems, in particular the Danube and Rhine (Smalley et al. 2008). This may include the slopes of surrounding mountains as well as fluvial terraces. Dry and cold conditions are generally assumed to lead to relatively high accumulation rates of loess, whereas during warmer and more humid environmental conditions vegetation cover prevents clastic silt production as well as ablation; soils develop on the loesses. Though sedimentation rates may differ with climatic conditions, loess-palaeosol sequences may represent high resolution geoarchives of past climatic conditions (e.g. Heller & Evans 1996). Loess does not only record palaeoclimate, but "can record short-term features of the Earth's magnetic field" (Zhu et al. 2006, in reference to Chinese loess). Further, loess may preserve archaeological remains in extraordinary quality because: 1) stratigraphical information of finds may be preserved as different cultural layers, 2) the imbedding in the loess prevents later disturbances of artefacts, and 3) the calcareous loess and its geochemical properties give the chance to find relatively unweathered artefacts in sediments (sensu Händel et al. in press).

The Earth's magnetic field (EMF) has a dominant dipole component, which is assumed to be geocentric in a time average. Non-dipole components exist additional to the dipole. The geomagnetic field may therefore be described as the sum of a dipole component and non-dipole components. The Earth's magnetic field undergoes changes in direction and amplitude in different time scales, and switches its polarity.

Secular variation describes the time variation of both the direction and intensity of the Earth's magnetic field with time on time scales up to 1 000 years. It includes both dipole and non-dipole components, which may be local. Secular variation is globally not uniform, but shows similar patterns on a "sub-continental" scale (e.g. Butler 1992). Therefore secular variation patterns should only be compared in the same region.

In cases of so called geomagnetic excursions the Earth's magnetic field changes its direction up to a reversed polarity for a short time period ($\leq 3\,000$ years in full reversed state), but re-establishes in its previous position, because the magnetic field in the inner core is not completely reversed (Gubbins 1999). Geomagnetic excursions show low magnetic field intensities and high directional deviations from an axial dipole field (Laj & Channell 2007). The so called Mono Lake (ca. 32-34 ka) and Laschamp (ca. 41 ka) excursions represent the most important palaeomagnetic time markers of the last glacial cycle and were recognised worldwide.

Sediments may preserve the magnetic field vector, consisting of direction and intensity of the magnetic

field during or shortly after deposition. The magnetisation process for loess is not fully understood (e.g. Zhu et al. 2006), various theoretical models are discussed. Liu et al. (2003) (in reference to Chinese loess) believe that the loess characteristic remanent magnetisation is a (post)depositional remanent magnetisation. It is assumed to be acquired shortly after deposition, and is therefore able to record magnetic field variations even on time scales of $\leq 1\,000$ years.

Relative palaeointensity (RPI) records provide a measure of the variability of the strength of the Earth's geomagnetic field at a given point on the Earth's surface. It may be obtained from sediments, whereas absolute palaeointensities may only be obtained from strongly heated material as e.g. volcanic rocks, hearths and (ancient) pottery. The RPI is calculated by normalising a stable component of the natural remanent magnetisation by a concentration-related rock magnetic (RM) parameter (sensu Tauxe 1993, 1998), as the magnetic susceptibility, the anhysteretic remanent magnetisation (ARM) or the isothermal remanent magnetisation (IRM). The calculated RPI ideally represents the relationship of acquired magnetisation to the ability to acquire a magnetisation. The relative variations of this signal are thought to represent the intensity variations of the Earth's magnetic field during or shortly after sediment deposition. Among other quality criteria, one of the most important ones is the affectedness by environmental and mineralogical changes. Tauxe (1993) suggested that records where the variation of RM parameters exceeds an order of magnitude should be avoided.

Palaeomagnetic dating also called magnetic stratigraphy includes all approaches dealing with the temporal variation of the direction as well as with the intensity of the EMF on time scales from 10^2 to 10^7 years. The magnetic stratigraphic investigation is a helpful tool in the age determination of sedimentary sequences. However for higher resolution records Stoner et al. (2002) state that "paleointensity can provide a global correlation tool at a resolution unattainable from isotope data alone". Hambach et al. (2008a) discuss magnetic dating with emphasis to the Quaternary. Magnetic stratigraphy provided first age control on many loess sites. In this context the Mono Lake, Laschamp and other geomagnetic excursions may be employed as important time markers for these sediments. Nawrocki et al. (1999) demonstrated that palaeomagnetic directional pattern comparison may be used for the correlation of European loess sequences. Geomagnetic excursions as time markers in loess were already successfully employed by e.g. Reinders & Hambach (1995) and references therein.

At the archaeological site of Poiana Cireşului near Piatra Neamt in Northeastern Romania we have the opportunity to date Gravettian cultural remains (charcoal, bones) by the way of ^{14}C and luminescence, and gain a palaeomagnetic RPI signal from the same

sediment. This way we combine numerical dating techniques with the palaeomagnetic signal at this site, which is a rare opportunity for terrestrial sedimentary sequences of this resolution.

Geological setting

The archaeological site of Poiana Cireşului is located near Piatra Neamt in eastern Romania, in the eastern proximity of the Carpathians. The archaeological excavation is one of numerous archaeological sites in the Bistriţa valley, it is situated at the southern edge of the Bistriţa valley at $\sim 46^{\circ}55' N$ and $\sim 26^{\circ}19' E$. Figure 1 gives the location of the archaeological site in a regional context. The site is situated southeast of the confluence of the Bistriţa and Doamna waters. The Poiana Cireşului archaeological site is situated at the edge of a terrace, and represents a rim structure between the terrace slope toward the Bistriţa valley and a land slide scar rectangular to the slope towards the rivulet Doamna. The site is situated on an erosional terrace of the Bistriţa, which was cut in Neogene flysch strata. The stratigraphic sequence at Poiana Cireşului is similar to the general stratigraphic succession of the middle terrace (pointed out by Nicolăescu-Plopşor et al. 1966). As the site is located on a rim structure, the depth of both palaeosols and

cultural layers differs spatially and with the topography. The loess imbedding cultural layers was most probably blown out of the flood plains of the Bistriţa valley, and covers its edges and the lower parts of the enclosing mountains. At the Poiana Cireşului site, the loess has a thickness of up to ca. 8 metres, and includes palaeosols and layers of redeposited loess (Carciumaru et al. 2006). The stratigraphy is not uniform in the proximity of the excavation; figure 2 depicts the stratigraphy of the western excavation wall of the 2006 excavation. Palaeomagnetic sampling was carried out a few meters to the north from the crest of the ridge where the youngest loess is best developed. Under the recent soil, a loess layer exists above a reddish cambisol which shows strong hydromorphic overprint caused by a gelistagnic water regime. The transition between decalcified (top) and calcified (bottom) loess is situated little below the soil; our sampling started in the calcified loess. An Epigravettian cultural layer (Epigravettian II) is present in the excavations at a stratigraphical position just below the decalcification level at the crest of the ridge. Below this stratigraphic level, loess of more yellowish to brownish colours occurs, and is intercalated by a Gravettian (Gravettian II) cultural layer around 390 cm depth, which corresponds to the peak in the magnetic susceptibility. Around 480 to 510 cm the loess is more

Rechts ist die magnetische Suszeptibilität des beprobten Intervalls dargestellt, die Gravettien II Kulturschicht zeigt ein deutliches Suszeptibilitäts-Maximum. *: Sedimentationsraten sind im oberen Teil des für die Paläomagnetik beprobten Intervalls, das am Hang liegt, niedriger als im dargestellten Referenzprofil, welches das Depozentrum am Kamm des Rückens repräsentiert.

humiferous and some charcoal was found, which may indicate incipient soil formation and human occupation. The lower part (from ca. 6 m downward) of the site appears to be spatially relatively inhomogeneous, in boreholes charcoal remains and more than one depth interval with redeposited loess was found (Carciumaru et al. 2006, Fig. 5). For the evaluation of the Upper Palaeolithic chronology in the Bistrița valley we refer to Steguweit et al. (this volume).

For this study a depth interval of 334 cm of relatively unaltered loess was sampled. Figure 2 gives a schematic stratigraphy of the sampled wall. The sampling was done approximately 4 m north of the plotted profile where the sedimentation rates are lower than in the stratigraphic plot for the upper part

of the sampled section (as indicated in Fig. 2). We plot lithology and magnetic parameters vs. the depth below the surface level of the plotted sequence, which may not be comparable to other profiles from the site due to the spatial inhomogeneity of the site. However, cultural layers may be taken as time/depth markers.

Methods

Palaeomagnetic procedures were applied on oriented specimens to reliably determine estimates for the strength of the palaeomagnetic field. This relative palaeointensity data set is compared with reference data, and this way is used to constrain existing age determinations for the site.

Oriented specimens were taken from the archaeological site using brass tubes and an orientation holder. Full spatial orientation is provided by magnetic compass measurements. Samples were taken with an edge length of 2 cm each, giving 8 cm³ samples. 160 samples were taken with a spacing of 2,1 cm between sample centres, giving a sampling extent of 336 cm. The oriented samples were stored in a μ -metal box until measurements began, and were stored in this box between measurements in order to shield samples against the EMF and laboratory fields.

Magnetic low-field susceptibility measurements were made employing an AGICO KLY-3S kappabridge. The frequency dependence of the magnetic susceptibility was determined from measurements at 300 Hz and 3 kHz using a MAGNON VF5M. Here the $((\kappa@0.3\text{kHz}-\kappa@3\text{kHz})/(\kappa@0.3\text{kHz}))*100$ is taken as measure for the frequency dependence of the magnetic susceptibility.

The 3-dimensional magnetisation was measured using an AGICO JR-6A spinner magnetometer. Alternating field demagnetisation was done in seven/eight steps up to 40/50 mT.

ARMs were produced along one spatial axis with a 100 mT alternating field (AF) and a 50 μ T static field applied simultaneously using a Magnon AFD 300. Resulting magnetisations were measured, then samples were demagnetised in the same spatial direction with 20 mT alternating field intensity (and no static field). The resulting magnetisations were measured.

IRMs with pulse field intensities of 2 T and 350 mT (back-field) were produced along one spatial axis using a MAGNON PM II pulse magnetiser, the resulting magnetisations were measured.

To obtain mass normalisation we normalise data given by instruments by the density in kg/m³.

Optically stimulated luminescence (OSL) dating was carried out on silt-sized quartz grains to get burial ages of one sample from above the Epigravettian II cultural layer. The sample was treated with HCl and H₂O₂ to remove carbonate and organic matter. Quartz grains of a diameter of 38–63 μ m were extracted by wet sieving, followed by a 14- to 20-day treatment

with 35% hydrofluorosilicic acid (H_2SiF_6). The grains were then deposited on aluminium discs and were measured on a Risø TL-DA-15 reader, equipped with a $^{90}Sr/^{90}Y$ beta source (dose rate of 0.14 Gy/s). Stimulation was performed using blue diode light of a wavelength of 470 ± 20 nm, while the resulting OSL signal was detected within the ultraviolet part of the spectrum between 260 and 390 nm (filter U340, thickness 7.5 mm). The single aliquot regenerative-dose protocol (SAR) according Murray & Wintle (2000) was applied using a modified cutheat temperature (cutheat: 220 °C, preheat: 240 °C for 10 s).

Alpha counting was carried out to quantify the U and Th content of the sediment, whereas the K content was measured via inductively coupled plasma-mass spectrometry (ICP-MS). The contribution of alpha radiation to the environmental dose rate is dependent on the alpha particle track length in the mineral. Hence, an alpha efficiency factor (a-value) has to be defined, expressing the ratio of luminescence per unit alpha track length to the luminescence per unit absorbed beta dose (Aitken & Bowman 1975). Rees-Jones (1995) determined a mean a-value of 0.04 for fine grained quartz, other authors later on found slightly lower mean values of 0.03 on silt-sized quartz (Mauz et al. 2006) or 0.035 on quartz extracted from Chinese loess (Lai et al. 2008). In the present study, the alpha efficiency was not determined experimen-

tally but the a-value of 0.035 ± 0.03 suggested by Lai et al. (2008) was used.

Computing of correlations was done using the R software package (Ihaka & Gentleman 1996). ^{14}C data were calibrated using CalPal-2007^{online} (Danzeglocke et al. 2008) with the Weninger & Jöris (2008) calibration data. All ages are given in calendric ages, if not noted otherwise.

Results and discussion

Rock magnetic properties

The variation of the rock magnetic parameters magnetic susceptibility, ARM, saturation IRM (SIRM, IRM @ 2 T), intensity of the 20 mT demagnetisation step (J_{20}), the mean destructive field (MDF), the frequency dependence of the magnetic susceptibility, the ARM/susceptibility ratio, and the ARM/SIRM ratio with depth are plotted in figure 3. The correlation matrix for the RM parameters employing the Pearson (Pearson 1896) correlation method tested for significance (after Best & Roberts 1975) is displayed in figure 4.

The concentration related parameters magnetic susceptibility, ARM and SIRM have a high analogy and correlate with a minimum correlation coefficient of 0.42 significantly, high values with $533 [10^{-9} m^2/kg]$ (susceptibility), $26 [10^{-6} Am^2/kg]$ (ARM) and

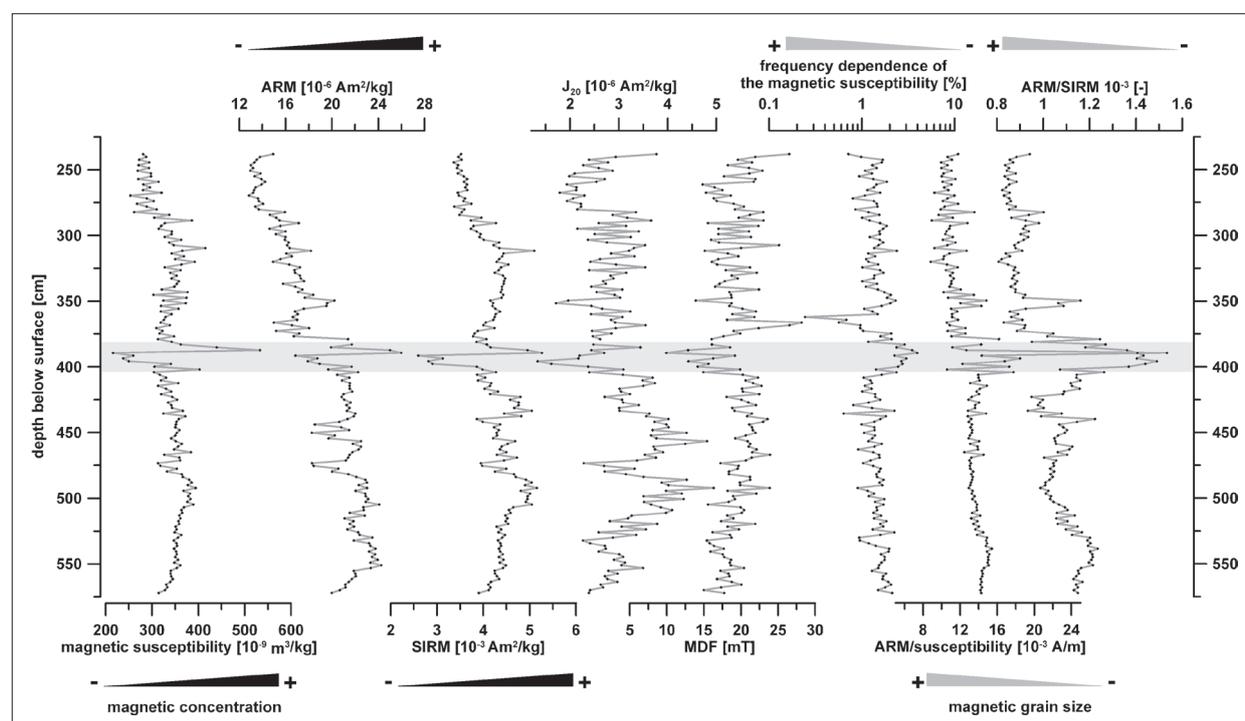

Fig. 3. Variation of rock magnetic parameters (abscissas) with stratigraphic depth (ordinate). From left to right: the magnetic susceptibility, the ARM, the SIRM, the J_{20} , the MDF, the frequency dependence of the magnetic susceptibility, the ARM/susceptibility ratio and the ARM/SIRM ratio. The cultural layer is shaded grey. Interpretations of these parameters as representative for magnetic concentration (left, black triangles) and magnetic grain size (right, grey triangles) are plotted.

5.3 [10⁻³ Am²/kg] (SIRM) occur within a cultural layer around 390 cm depth. Below this cultural layer these concentration related parameters (susceptibility, ARM, SIRM) tend to have higher values than above. The J₂₀ has a distinct pattern; the uppermost ca. 60 cm have relatively low values. From ca. 280 cm to ca. 380 cm depth the J₂₀ signal has no trend, but a local minimum around 350 cm depth. The global minimum

of the J₂₀ occurs at ca. 390 cm. An increasing trend exists to ca. 460 cm, which is disturbed by a local minimum around 425 cm. A relative minimum from ca. 460 cm to ca. 490 cm occurs, hereafter the magnetisation increases again and peaks around 495 cm. A decreasing trend in magnetisation is observed until the end of the sampled section, which is disturbed by a minimum around 525 cm. The MDF does not show

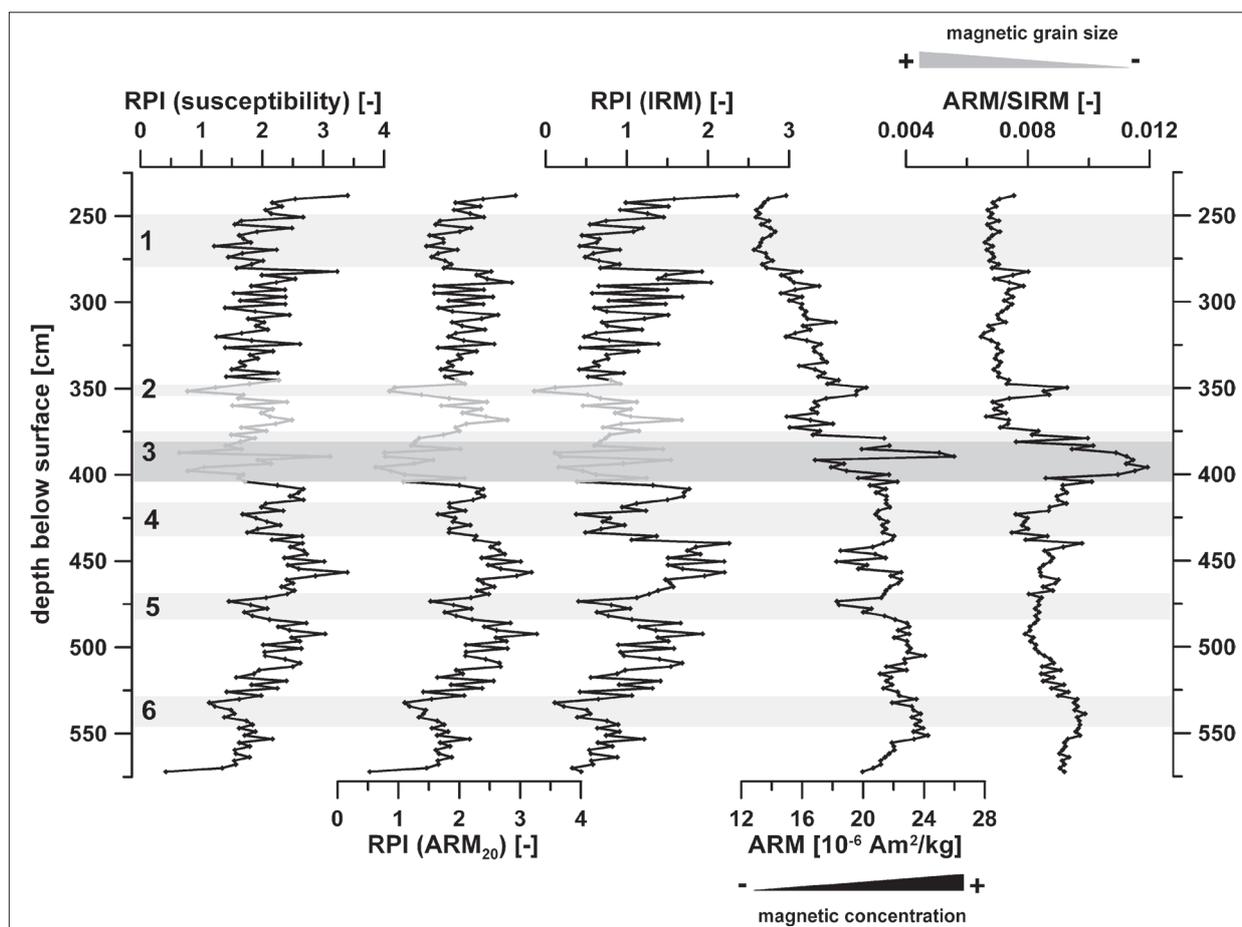

Fig. 5. The variation of the RPIs normalised by the magnetic susceptibility, ARM₂₀ and SIRM (abscissas) is given as function of depth (ordinate). The ARM and ARM/SIRM ratio are plotted on the right for comparison. Depth intervals with relative RPI minima are shaded in grey and numbered, the cultural layer is shaded in darker grey. For the interval of varying magnetic grain size the RPIs are plotted in grey.

Abb. 6. Streudiagramme der ARM_{20} , der magnetischen Suszeptibilität und der SIRM, aufgetragen gegen die RPI J_{20}/ARM_{20} .

much amplitude, most values are between 12 and 24 mT. All rock magnetic parameters show relatively little variation (a factor of ~ 3 at maximum) and the interval around the cultural layer appears to have the highest deviations from average values.

The magnetic susceptibility, ARM and SIRM are taken as indicative for the concentration of magnetic matter within the sediment, whereas the frequency dependence of the magnetic susceptibility, the ARM/susceptibility and the ARM/SIRM ratios may be taken as indicative for the magnetic grain size with higher values representing a higher amount of small superparamagnetic particles.

Rock magnetic parameters obviously vary within the Poiana Cireşului section. The concentration related parameters show a trend of increasing amounts of magnetic matter with depth, whereas the grain size related parameters show no trend but relatively high variations between 345 and 400 cm. The depth interval around the cultural layer between 350 and 410 cm is the only depth interval with distinctly abnormal values of the concentration- and grain size-related parameters.

The relative palaeointensity

The RPI is determined using different normalisation methods. The J_{20} is chosen for normalisation because overprints were reliably removed by 20 mT AF demagnetisation, and this demagnetisation step still obtains a reasonable amount of magnetisation. For RPI determination, input parameters are detrended, then the RPI is normalised to a mean of 2 and a standard deviation of 0.5. The J_{20} is normalised by 1) the susceptibility 2) the ARM demagnetised at 20 mT (ARM_{20}) and 3) the SIRM. Results are plotted in figure 5 together with the concentration related ARM as well as the grain size related ARM/SIRM ratio.

The RPI data sets obviously have similar trends. Relative minima (1-6 in fig. 5) occur around 270 cm, 350 cm, 375-405 cm, 425, 475 and 540 cm and are shaded grey. Relative maxima occur around 290 cm,

370 cm, 415 cm, 460 cm, 490 cm and 560 cm.

For the calculations of correlations, data from the obviously affected cultural layer are excluded. The RPI data sets correlate with a minimum correlation coefficient of 0.83 significantly. The high analogy and correlation of the different normalised RPIs suggests that the three normalisation methods each result in a realistic data set for the RPI. Further, normalising different demagnetisation steps give similar RPI estimates (not presented). The maximum norm correlation of a RPI (ARM_{20} -normalised) to a concentration related rock magnetic parameter (the magnetic susceptibility) is 0.33. Scatter plots of the ARM, the magnetic susceptibility and the ARM/SIRM ratio to the RPI estimate J_{20}/ARM_{20} are shown in figure 6, and reveal no obvious relations.

Though some quality criteria (in particular the sediment homogeneity within an order of magnitude and similar results using different normalisers) are met by the presented data, the depth interval around the cultural layer between ~ 350 and 410 cm may be affected by changes in the magnetic mineralogy, in particular the magnetic grain size. Therefore one has to treat RPIs from this depth interval with caution. However, all data not from the cultural layer are regarded reliable.

Age determination

The age estimation of the Poiana Cireşului section is accomplished by the combination of different methods. AMS ^{14}C dating was done for ten samples from three depths (one just above the sampled depth interval, one is the sampled cultural layer; one age is from a drilling core near the excavation, results are displayed in figure 7). The ^{14}C ages from the two cultural layers are each in reasonable agreement, though not in every case within the 1σ error bars of samples from the same stratigraphic horizon.

Luminescence dating of the last exposure to light was accomplished for one sample just above the Epigravettian II cultural layer. Data required for the

age determination and the dating results are presented in figure 8. The datum above the palaeomagnetically sampled interval of 22.66±1.81 ka supports the results of ¹⁴C dating.

RPI correlation

The palaeomagnetic palaeointensity correlation relies on a rough idea of the timing of the sediment deposition and therefore palaeomagnetic signal acquisition. In the case of this study the RPI signal may be correlated unambiguously above the cultural layer due to independent numerical dating.

The RPI (ARM₂₀ normalised) smoothed with a running average of three samples is compared to the GLOPIS (High resolution global paleointensity stack) compiled by Laj et al. (2004) and to RPI data from loess at Krems Wachtberg (Austria), presented by Hambach et al. (2008b).

The RPI minima numbered "2" and "3" within the grey shaded depth interval may be related to a similar counter-correlated pattern on the ARM/SIRM ratio, and therefore may be artefacts of changing magnetic properties, but may as well represent features of the palaeomagnetic field. We interpret the RPI pattern of this interval not to be the result of only changing rock magnetic properties, but at least partly to be the result of the palaeomagnetic field. The little variations in the rock magnetic properties (a factor of ~3 at maximum), the similarity of different normalisation methods, and no correlation of the RPI to concentration related parameters speak for this interpretation. Further, no significant correlation between the J₂₀ and the ARM/SIRM can be established for the whole data set (see Fig. 4), this way we can exclude the grain size variation as systematically biasing factor for the magnetisation for the whole data set. Though a bias in some intervals can not be excluded, we interpret the

RPI signal as mainly the result of magnetic field intensity variations.

Following this idea, relatively low RPIs numbered 1 - 6 in figure 5 are correlated to distinct RPI features of the GLOPIS, as plotted in figure 9, ages obtained from this correlation are displayed in figure 10. The uppermost "1" RPI minimum is correlated to a minimum of the GLOPIS around 26 ka (on the GISP2 time scale of the GLOPIS). The "2" RPI minimum at ~350 cm depth is assigned to a minimum of the GLOPIS around 30 ka. The global RPI minimum is correlated to the GLOPIS minimum corresponding to the Mono Lake geomagnetic excursion at ca. 34 ka. The RPI minima "4" and "5" cannot be matched to the GLOPIS. Other high resolution RPI data sets (see e.g. Krems Wachtberg) of this time interval show RPI minima between the Mono Lake and Laschamp excursions. The correlation of the RPI minimum "6" to the Laschamp is reasonable if a similar sedimentation rate is assumed all over the profile. In most data sets, the Laschamp shows lower RPIs than the Mono Lake, therefore the "4" and "5" RPI minima are not suggested to represent the Laschamp. If one interpreted the interval between the "2" and "3" RPI minima as affected by changes in mineralogy, and therefore unsuitable for RPI determination, one might interpret the RPI minimum "4" as the Mono Lake. This would not imply major changes of the resulting overall sedimentation rate and the age model. The oldest ¹⁴C age from the drill (see Fig. 7) implies that the loess was deposited in MIS 3, and is not much older in the lower part. This supports our idea of semi-continuous sedimentation.

The sediment composition above and below the Gravettian II cultural layer is somewhat different, with more humiferous and dense sediment in the lower part of the section (below 450 cm). This may be taken

Sample ID [field]	Sample ID [lab]	Depth [m]	K [%]	U [ppm]	Th [ppm]	Water content [%]	ED [Gy ± 1σ]	Aliquot number	D [Cy/ka]	Age [ka]
PC 2	BT 499	1.2	2.18 ± 0.11	3.16 ± 0.16	11.31 ± 0.57	20 ± 5	77.7 ± 1.9	15	3.43 ± 0.26	22.66 ± 1.81

Fig. 8. Environmental radioactivity and OSL dating results. ED = Equivalent dose, D = Dose rate. Water content is given in percent of dry mass. Dose rate calculation includes the radiation emitted by K, U, Th, and cosmic dose. The alpha efficiency was taken as a = 0.035 ± 0.003 (Lai et al. 2008).

Abb. 8. Umweltradioaktivität und OSL-Datierungsergebnisse. ED = Äquivalenzdosis, D = Dosisrate. Der Wassergehalt ist in Prozent der Trockenmasse angegeben. Die Dosisleistungsberechnung beinhaltet K, U, Th und kosmische Strahlung. Der a-Wert wurde mit a = 0.035 ± 0.003 angenommen (Lai et al. 2008).

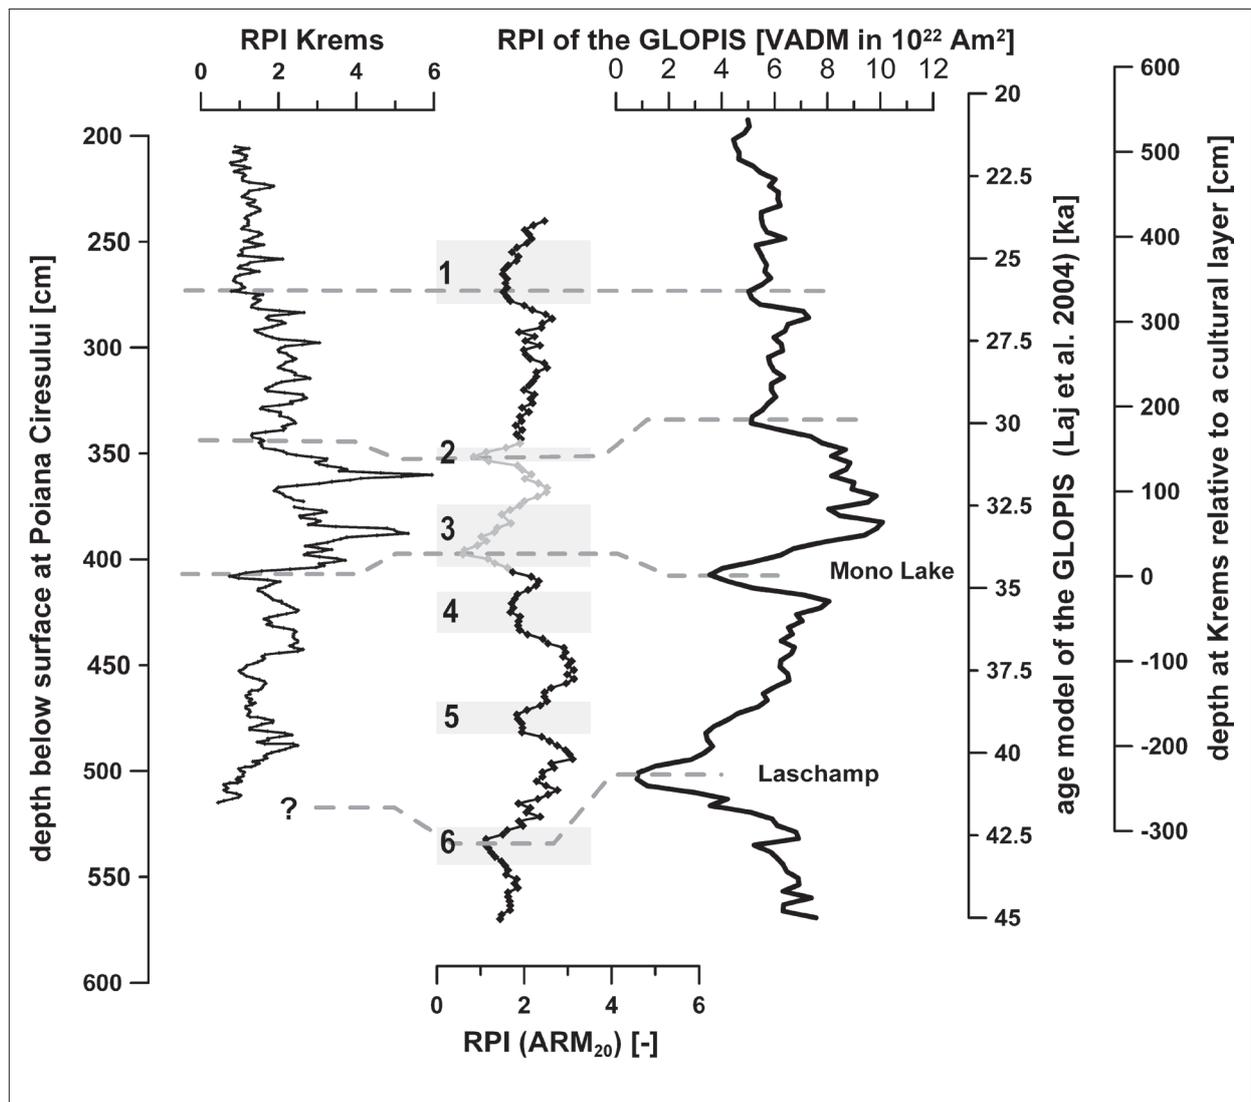

Fig. 9. Comparison of the RPI variations from Poiana Cireşului (middle) with the GLOPIS (right) and data from Kreams (left). Suggested correlations are indicated by the dashed lines, one questionable correlation is marked by the question mark. For the GLOPIS the VADM (virtual axial dipole moment) is given as unit of the strength of the Earth's magnetic palaeofield. The RPI lows of figure 5 are plotted as grey intervals with the corresponding numbering.

Abb. 9. Vergleich der RPI aus Poiana Cireşului (mitte) mit dem GLOPIS (rechts) und Daten aus Kreams (links). Vorgeschlagene Korrelationen sind durch gestrichelte Linien gekennzeichnet, eine unsichere Korrelation ist durch das Fragezeichen gekennzeichnet. Für den GLOPIS ist das VADM (virtuelle axiale Dipolmoment) als Einheit des Paläoerdmagnetfeldes angegeben. Die Intervalle geringer RPI sind mit entsprechender Nummerierung aus Abbildung 5 übernommen.

as indicator for (weak) pedogenesis or other post depositional alteration of the loess, maybe partly during the Denekamp interstadial complex (Greenland Interstadial/GI 5 to 8?). In this case sedimentation rates should be lower than during the cooler periods from the upper part of the sampled section. This should imply a change towards a lower

sedimentation rate in the lower part of the section, and therefore a higher increase in age with depth. If higher sedimentation rates occurred, the palaeomagnetic signal of the Laschamp should be seen within the Poiana Cireşului exposure, which is the case for the lowermost "6" RPI interval.

Our RPI correlation imposes similar or slightly higher sedimentation rates within the lower part of the Poiana Cireşului section, compared to the upper part. During a relatively warm climatic period including the Denekamp this is not particularly expected. If the Denekamp corresponds to the peak of concentration related rock magnetic parameters (in particular the SIRM) around 500 cm, the stratigraphical position below this interval supports the idea of the Laschamp.

method	depth [cm]	age [ka]	depth error [cm]	age error [kyr]
RPI	265	26	10	0.5
RPI	350	30	10	0.5
RPI	400	34	10	0.5
RPI	535	39	10	0.5

Abb. 10. Alter aus den Korrelationen der RPI.

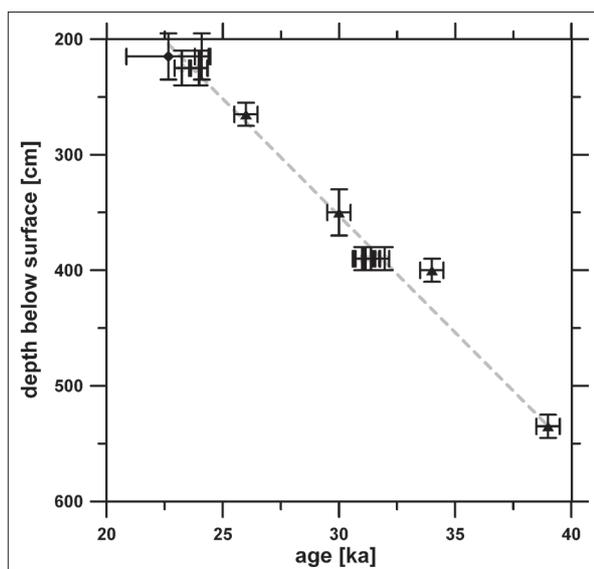

Fig. 11. Ages for the Poiana Cireșului section from AMS ^{14}C dating (circles), luminescence dating (diamond) and RPI correlation (triangles) with error bars. A linear fit to all points (unweighted) is represented by the grey dashed line.

Abb. 11. Bestimmte Alter des archäologischen Aufschlusses Poiana Cireșului. AMS ^{14}C (Kreise), das Ergebnis der Lumineszenzdatierung (Raute) und der RPI-Korrelation (Dreiecke) mit Fehlerbalken. Die gestrichelte Linie stellt eine (ungewichtete) lineare Regression durch alle Punkte dar.

The correlation to the GLOPIS works well for the Poiana Cireșului section (Fig. 9), the correlations presented here appear to be the most likely ones, and are in good agreement with ^{14}C and luminescence dating if available. Similar RPI features are observed in the Krems Wachtberg and Poiana Cireșului sections in European loess, which gives further confidence in our data.

The ages, employing above mentioned techniques, give a consistent age increase with depth. For the RPI correlation only metering errors as errors in age are accounted for, errors in depth originate in the unclear duration of palaeomagnetic features. Using all data, a mean sedimentation rate of ca. 20 cm/kyr may be approximated (dashed grey line in Fig. 11).

The duration of the RPI minimum taken as Mono Lake is ca. 1.3 kyr using a linear age model (dashed line in Fig. 9), and longer for the Laschamp when not the whole Laschamp was sampled. These estimates of duration are in the same range and in general agreement with reported durations of these geomagnetic excursions by e.g. Liddicoat & Coe (1979) (Mono Lake, "about 1 000 years"), Benson et al. (2003) (Mono Lake, "between 31 500 and 33 300 GISP2 yr BP") and Laj et al. (2004) (Mono Lake and Laschamp, "estimated to about 1 500 years"). Further, these durations lie within the suggested possible durations for geomagnetic excursions after Gubbins (1999).

In this study we show that the RPI correlation may improve age constraints for loess and loess like sediments. In this case the palaeointensity correlation method supports an existing age model, and gives

first insight into sediments not dated otherwise. The sediment homogeneity is a crucial prerequisite for the RPI determination. In this case we suggest that the sampled loess meets quality criteria, and we obtained a RPI data set. The correlation to reference data (in particular the GLOPIS) works well, and age determination is accomplished by the correlation of palaeomagnetic intensity features. As shown for the palaeomagnetic directional records of European loess sediments (Nawrocki et al. 1999, Reinders & Hambach 1995), we suggest that the RPI correlation is a helpful dating tool, if an approximate age is known from other (numerical) dating techniques. Obviously continuous, long data sets are required.

It appears that palaeomagnetic studies on loess have barely been carried out (in Europe), palaeomagnetic intensity studies are even scarcer. More reference data might improve the accuracy of possible correlations. However, this approach of loess dating may bring light not only into the timing of loess deposits, but may also improve the understanding of sedimentation rates of (archaeology bearing) loess, and its (ir)regularity.

Directional palaeomagnetic signal comparison probably may improve this signal-comparison-technique, but is much more time demanding.

Conclusions

This palaeomagnetic study carried out at the Poiana Cireșului archaeological site yielded a reliable RPI record in the intervals suitable for RPI determination. The RPI correlation is used together with numerical dating techniques to gain a consistent age model for the archaeological site. Ages obtained from RPI correlations (Fig. 9) are consistent with the results of numerical dating techniques (Figs. 7, 8 & 11). The comparison of the here presented data to both the GLOPIS and loess RPI data from Krems-Wachtberg works well.

Within the data from Poiana Cireșului we see a RPI minimum which we correlate to the Mono Lake excursion. In the lower part of the section we suggest to see the Laschamp excursion. This high-resolution RPI study clearly emphasises the yet largely undiscovered but high potential of archaeological sites (covered by loess) for palaeomagnetic studies. In this case palaeomagnetism, combined with other dating techniques, contributes to constrain an age model for an archaeology bearing sedimentary sequence.

ACKNOWLEDGEMENTS: We thank Carlo Laj and Catherine Kissel for sharing the GLOPIS data. The Bavarian Academic Center for Central, Eastern and Southeastern Europe (BAYHOST) supported field work (grant number I 120-01h). Constructive reviews by anonymous reviewers improved the quality of the manuscript.
